Classification of breast lesions with

high-resolution ultrasound. High-resolution ultrasound (HRU) has been used in the diagnosis of focal breast lesions for a number of years. It has been applied to a variety of breast lesions, and has been shown to have similar sensitivity and specificity to mammography in the diagnosis of ductal carcinoma in situ and invasive cancer. However, its efficacy in diagnosing various other types of breast lesions has not been thoroughly assessed. In this study, the authors performed a retrospective review of the breast histology results of 531 lesions examined with HRU (21-MHz flat-panel transducer; Model 10X, Sonics and Materials, Inc., Bloomfield, Conn.) to evaluate the efficacy of HRU in the characterization of lesions that are difficult to differentiate from masses. All lesions were detected by mammography and/or clinical

examination. Lesions were considered suspicious of malignancy on the basis of any one of the following criteria: a maximum dimension of 1.5 cm or greater, margins that were spiculated or obscured, a discrete irregular shape, or a circumscribed echogenicity similar to the spiculated appearance of calcifications seen on mammography.

A majority (58.1%) of the lesions studied were palpable. The majority of lesions were benign (n = 377), with 1,262 of the lesions having benign biopsy results. Of the remaining lesions (
